Sparse approximate solutions to stochastic Galerkin equations

Approximations creuses pour la méthode de Galerkin stochastique

In this Note, we formulate a sparse Krylov-based algorithm for solving large-scale linear systems of algebraic equations arising from the discretization of randomly parametrized (or stochastic) elliptic partial differential equations (SPDEs). We analyze the proposed sparse conjugate gradient (CG) algorithm within the framework of inexact Krylov subspace methods, prove its convergence and study its abstract computational cost. Numerical studies conducted on stochastic diffusion models show that the proposed sparse CG algorithm outperforms the classical CG method when the sought solutions admit a sparse representation in a polynomial chaos basis. In such cases, the sparse CG algorithm recovers almost exactly the sparsity pattern of the exact solutions, which enables accelerated convergence. In the case when the SPDE solution does not admit a sparse representation, the convergence of the proposed algorithm is very similar to the classical CG method.

R É S U M É

Dans cette Note, nous formulons une méthode de Krylov creuse pour la résolution de grands systèmes linéaires issus de la discrétisation d'équations aux dérivées partielles elliptiques aléatoirement. Nous analysons l'algorithme du gradient conjugué (GC) creux dans le cadre des méthodes de sous-espaces de Krylov inexactes, montrons sa convergence et étudions sa complexité algorithmique. Les études numériques réalisées sur des modèles de diffusion stochastiques montrent que la méthode du GC creux converge plus rapidement que le GC classique lorsque la solution recherchée admet une représentation creuse dans une base de chaos polynomial. Dans ce cas, l'algorithme du GC creux retrouve presque intégralement la structure creuse de la solution exacte, permettant d'accélérer la convergence. Lorsque la solution exacte est dense, l'algorithme du GC creux fournit des résultats de convergence similaires à ceux obtenus avec le GC classique.

1. Introduction

In computational engineering sciences, different sources of randomness (which typically appear in the physical parameters, boundary conditions and/or initial conditions of a partial differential equation) are routinely taken into account for uncertainty quantification purposes, for example for applications in fluid dynamics or heat transfer. The sources of randomness are commonly modeled using a finite number of random variables, leading to randomly parameterized (or stochastic) partial differential equations (SPDEs). In the present work, we focus on the numerical solution to large-scale linear algebraic systems of equations arising from spatial and stochastic discretization of SPDEs. As a typical example, consider the following stochastic steady-state diffusion equation with homogeneous Dirichlet boundary conditions

\[-\nabla \cdot (\kappa(x; \xi) \nabla u(x; \xi)) = f(x; \xi) \quad \text{a.s. in } D \times \Gamma,\]
\[u(x; \xi) = 0 \quad \text{a.s. on } \partial D \times \Gamma,\]  

where \(D\) is an open bounded domain of \(\mathbb{R}^d\) (\(d = 2, 3\)) with boundary \(\partial D\), and \(x \in D\) is the spatial variable. We denote the probability space by the triplet \((\Omega, \mathcal{F}, \mathbb{P})\), where \(\Omega \subset \mathbb{R}^d\) is the sample space, \(\mathcal{F}\) is the \(\sigma\)-algebra associated with \(\Omega\) and \(\mathbb{P}: \mathcal{F} \to [0, 1]\) is a probability measure. The components of the vector \(\xi = (\xi_1(\omega), \ldots, \xi_M(\omega))^T \in \mathbb{R}^M\), where \(\omega \in \Omega\), are assumed to be i.i.d. random variables. The joint probability density function (pdf) of \(\xi\) is denoted by \(\rho(\xi)\) and can be written as the product of its marginal densities, that is \(\rho(\xi) = \prod_{j=1}^M \rho_j(\xi_j)\). We denote by \(\Gamma = \Gamma_1 \times \cdots \times \Gamma_M\) the joint image of \(\xi\). The diffusivity field is classically discretized using a truncated Karhunen–Loève (KL) expansion scheme [17] as \(\kappa(x; \xi) = k_0(x) + \sum_{m=1}^M \xi_m k_m(x)\), where \(k_0\) is the mean diffusivity and \((k_m)_{m \geq 1}\) forms an orthogonal basis of \(L^2(D)\). The functions \(k_m\) are defined as \(k_m = \sigma \sqrt{\lambda_m} \psi_m\), where \(\sigma\) denotes the standard deviation of \(\kappa\) and \((\lambda_m, \psi_m)\) are the eigenpairs of the two-point correlation function used for modeling the diffusivity field. Using Doob–Dynkin’s lemma [20], it can be shown that the SPDE solution can be described with the same set of random variables used for representing \(\kappa\), that is, \(u = u(x; \xi_1(\omega), \ldots, \xi_M(\omega))\).

In recent years, various numerical schemes have been developed for solving SPDEs, including polynomial chaos (PC) stochastic Galerkin projection schemes [13,32] and stochastic collocation schemes based on sparse tensor product quadrature rules [31]. In the present work, we focus on stochastic Galerkin methods where approximate solutions are sought in finite-dimensional tensor product subspaces \(\mathbb{P}_{x,h} \otimes \mathbb{P}_{\xi,P_\xi}\), where

\[
\mathbb{P}_{x,h} = \text{span}\{\phi_i(x)\}_{i=1,\ldots,N_x} \subset H^1_0(D), \quad \mathbb{P}_{\xi,P_\xi} = \text{span}\{\psi_i(\xi)\}_{i=1,\ldots,N_\xi} \subset L^2(\Gamma).
\]  

Typically, \(\phi_i\) denote piecewise linear continuous finite element (FE) basis functions defined on a triangulation of \(D\) and vanishing on \(\partial D\). Using the multi-index notation \(\alpha = (\alpha_1, \ldots, \alpha_M) \in \mathbb{N}^M\), PC basis functions are given by \(\psi_\alpha(\xi) = \prod_{j=1}^M \psi_{\alpha_j}(\xi_j)\). The set of multivariate PC basis functions of total degree \(p_\xi\) is then defined as \(\mathbb{P}_{\xi,p_\xi} = \text{span}\{\psi_\alpha(\xi)\}, \ |\alpha| = \alpha_1 + \cdots + \alpha_M \leq p_\xi\), which is of dimension \(N_\xi = \binom{M+p_\xi}{M+p_\xi}\). For notational convenience, PC basis functions are often reordered using a one-to-one mapping as \(\psi_\alpha(\xi), \ i = 1, \ldots, N_\xi\). The application of stochastic Galerkin projection schemes (also referred to as spectral FE methods) leads to deterministic \(N_xN_\xi \times N_xN_\xi\) linear algebraic equations of the form

\[A u = b,\]

where \(A\) has the characteristic Kronecker product structure

\[A = G_0 \otimes A_0 + \sum_{m=1}^M G_m \otimes A_m,\]

with \(G_m \in \mathbb{R}^{N_x \times N_\xi}\) and \(A_m \in \mathbb{R}^{N_\xi \times N_\xi}\). In the case of the stochastic diffusion models described above, the matrix entries are given by \((G_0)_{ij} = (\psi_i \psi_j), \ (G_m)_{ij} = (\xi_m \psi_i \psi_j), \ (A_0)_{ij} = \int_D k_0(x) \nabla \psi_i(x) \nabla \psi_j(x) \, dx\) and \((A_m)_{ij} = \int_D k_m(x) \nabla \psi_i(x) \nabla \psi_j(x) \, dx\), where the notation \((\cdot)\) stands for the expectation operator with respect to \(\rho\), i.e. \(\langle \cdot \rangle = \int_D \cdot \, d\rho\).

From a theoretical point of view, there has been a growing interest in the analysis of PC-based Galerkin projection schemes with the derivation of a priori rates of convergence; see, for example, [2,3,8,29]. Randomly parameterized linear algebraic equations (corresponding to the spatial semi-discretization of SPDEs) have been analyzed and studied numerically in [1,7,9,10]. In realistic engineering applications (for example, 3D stochastic diffusion models where vast numbers of random variables are needed to accurately model the diffusivity field), the expanded matrix equations (3) become extremely large, since both \(N_x\) and \(N_\xi\) are large (\(N_\xi\) increases exponentially with \(M\) and \(p_\xi\)). This has motivated the development of efficient numerical techniques (e.g., [18,19,23]) and efficient preconditioning strategies (e.g., [21,22,28,30]).

In the present work, we focus on sparse approximations of large-scale stochastic Galerkin matrix equations, that is, we seek a sparse approximate solution \(\hat{u}\) such that

\[\| \left( G_0 \otimes A_0 + \sum_{m=1}^M G_m \otimes A_m \right) \hat{u} - b \|_2 \leq \varepsilon,\]
where $\varepsilon$ is a given threshold. Sparse approximation algorithms based on $\ell_1$ or $\ell_2$ regularizations are widely used in machine learning and compressive sensing while solving multivariate regression problems with noisy datasets, the sparsity being used to filter the noise in the training data [6,11,12,16]. The idea of sparse approximations has also been used in various other contexts to alleviate the curse of dimensionality, for example, sparse quadrature rules [31] based on Smolyak’s construction, sparse approximations for transport-dominated diffusion problems [24], and stochastic Galerkin approximation based on sparse wavelet bases for the Boltzmann equation with uncertainties [25].

In the context of stochastic Galerkin equations, our goal is to formulate a sparse version of the classical Krylov methods, namely the conjugate gradient (CG) algorithm. Since the expanded matrix equations (3) are deterministic, the sparsity feature is not used to filter the noise, but to improve computational efficiency and reduce memory requirements. Using sparse Krylov-based algorithms to solve stochastic Galerkin matrix equations also allows to exploit the sparsity feature that is inherent to some SPDE solutions and accelerate the convergence speed. It is worth noting that PC approximations of some stochastic diffusion models can be shown to be sparse in nature [5]. We carry out a convergence analysis of the proposed sparse CG algorithm by interpreting it as an inexact Krylov method. Numerical studies are presented for a set of test problems to illustrate that the proposed algorithm can recover almost exactly the sparsity pattern of the exact solution, while incurring computational expense that is lower than with the classical CG algorithm. In cases where the exact solution does not admit a sparse representation in a PC basis, the performance of the proposed algorithm coincides with the classical CG algorithm.

2. Sparse CG algorithm

We propose a sparse CG algorithm for solving (3)–(4) in the case when $A \in \mathbb{R}^{N_X N_\xi \times N_X N_\xi}$ is a symmetric positive-definite (SPD) matrix. The main idea is to start with a sparse initial guess $u_0^0 \in \mathbb{R}^{N_X N_\xi}$ and generate iterates of the form $u^{k+1} = u^k + \alpha_k p^k$, where $p^k \in \mathbb{R}^{N_X N_\xi}$ are (very) sparse search directions and $\alpha_k$ denotes the step length. Typically, a random initialization of the $N_\xi$ first components is used, which corresponds to considering a deterministic approximation to the SPDE solution. Since $A$ is SPD, solving (3) is equivalent to minimizing the quadratic objective function $F(u) = \frac{1}{2} \langle (A u, u) - \langle u, b \rangle \rangle$, which justifies the natural choice of the step length:

$$
\alpha_k = \arg\min_{\alpha \in \mathbb{R}} F(u^k + \alpha p^k) = \frac{(p^k, r^k)_2}{(Ap^k, p^k)_2},
$$

where $r^k = b - Au^k$. At the $k$-th iteration, the search direction is defined as $p^k = m^k \circ z^k$, where the preconditioned residual $z^k \in \mathbb{R}^{N_X N_\xi}$ is known to be a descent direction, $m^k \in \mathbb{R}^{N_X N_\xi}$ is a sparsifying mask (i.e. a vector that only contains zeros and ones), and $\circ$ denotes the Hadamard (or element-wise) product between vectors. The initial sparse mask is defined with ones for its first $N_\xi$ components. It is worth mentioning that the $A$-conjugacy property for the search directions as well as the residual orthogonality with respect to the Krylov subspace do not hold anymore since a sparse mask is applied to the search direction at each iteration. Consequently, it is not possible to use classical CG updates of the form $p^{k+1} = z^{k+1} + \beta_k p_k$. Hence, a modified Gram–Schmidt (MGS) procedure is used to enforce the conjugacy of $p^{k+1}$ with respect to the preceding $l$ search directions $(p^j)_{j=k-l,\ldots,k}$, where $l$ is kept small for memory and computational savings.

A key ingredient of the sparse CG algorithm is the strategy used to define new search directions. The simplest way to determine a new index (or a set of indices) in the sparse mask is to find the largest component(s) in the current residual, among the indices that have not yet been selected. However, numerical studies suggest that this criterion is problem-dependent – the number of new entries to add in the sparse mask that ensures fast convergence can vary significantly, depending on the test case; also, setting the “right” number of entries beforehand is not straightforward in practice. For more flexibility, we choose new entries in the sparse mask by selecting among a set of indices the residual components that are larger than a given threshold, where the threshold parameter is dynamically updated across iterations. More precisely, if $J^k$ denotes a set of indices that have not yet been selected, the new entries are defined as $I_{k+1} = \{ i \in J^k : |r^k_i| > \theta \}$. The threshold $\theta$ is initialized with a large value and then automatically decreased when no (or not enough) additional entries can be selected, that is, if $|I_{k+1}| < \theta_{init}$. Since the classical CG stopping criterion $||r^k||_2 > \varepsilon ||r^0||_2$ is ensured if

$$
||r^k||_2 \geq \sum_{i=1}^{N_X N_\xi} \left(\frac{r^k_i}{|r^k_i|}\right)^2 \geq \sqrt{N_X N_\xi} \min_i |r^k_i| > \varepsilon ||r^0||_2,
$$

it naturally provides the lower bound $\theta_{cg} = \varepsilon ||r^0||_2 / \sqrt{N_X N_\xi} \leq \theta$. The main steps of the sparse CG algorithm (using a preconditioner $M$) are outlined below.

Preconditioned sparse CG ($A$, $b$, $M$, $N_x$, $N_\xi$, $\varepsilon$, $\theta_{init}$, $l$)

Define $u^0 = (u_1, u_2, \ldots, u_{N_X}, 0, 0, \ldots, 0)^T$ and $r^0 = b - Au^0$.

$m^0 \leftarrow (1, 1, \ldots, 1, 0, 0, \ldots, 0)^T$

$\theta^0 \leftarrow \{N_X + 1, \ldots, N_X N_\xi\}$

Define $u^0 = (u_1, u_2, \ldots, u_{N_X}, 0, 0, \ldots, 0)^T$ and $r^0 = b - Au^0$.

$m^0 \leftarrow (1, 1, \ldots, 1, 0, 0, \ldots, 0)^T$

$\theta^0 \leftarrow \{N_X + 1, \ldots, N_X N_\xi\}$
Solve $Mz^k = r^k$
$p^0 = m^0 \circ z^0$
$\theta \leftarrow \theta_{\text{init}}$
$\theta_{cg} = \epsilon \left| r^0 \right|_2 / \sqrt{N_X N_\xi}$
$k \leftarrow 0$

\begin{algorithm}
while \((\left| r^k \right|_2 / \left| r^0 \right|_2 > \epsilon)\) do

$\alpha_k = \langle p^k, r^k \rangle_2$
$u^{k+1} \leftarrow u^k + \alpha_k p^k$
$r^{k+1} \leftarrow r^k - \alpha_k Ap^k$

Solve $Mz^{k+1} = r^{k+1}$
Select $I_{k+1} = \{i \in J_k \mid |r^k_i| > \theta, |I_{k+1}| = m_k \}
$m^{k+1} \leftarrow m^k + \sum_{j \in I_{k+1}} e_j$
$j^{k+1} \leftarrow J_k \setminus I_{k+1}$

if \(|I_{k+1}| \leq \delta_\nu\) then
$\theta \leftarrow \theta / 10$
if \(\theta < \theta_{cg}\) then
$\theta \leftarrow \theta_{cg}$
end if
end if

$p^{k+1} \leftarrow m^{k+1} \circ z^{k+1}$
$p^{k+1} \leftarrow \text{MGS}(p^{k+1}, (p^j)_{j=k-1,\ldots,k})$
$k \leftarrow k + 1$
end while

3. Computational aspects and analysis

3.1. Computational cost and storage

We compare the classical and sparse CG algorithms in terms of abstract computational cost and memory requirements. For simplicity, we consider non-preconditioned versions of both algorithms, where the computational cost at each iteration is dominated by matrix-vector products. Since $A$ has a Kronecker product structure (see (4)), the matrix-vector product $y = Ap^k$ can be efficiently computed as

$$y = \left( \sum_{m=0}^{M} G_m \otimes A_m \right) p^k = \text{vec} \left( \sum_{m=0}^{M} A_m p^k G_m^\top \right),$$

(8)

where $p^k = [p^k_1, \ldots, p^k_{N_k}] \in \mathbb{R}^{N_A \times N_\xi}$ contains the $N_\xi$-dimensional PC component vectors of $p^k$, and vec is the columnwise vectorization of matrices. In classical CG algorithms, the cost per iteration is essentially $O(\sum_{m=0}^{M} \text{nnz}(A_m) N_\xi + \text{nnz}(G_m) N_A)$. Assuming that $A_m$ and $G_m$ have the same sparsity profile, that is, $\text{nnz}(A_m) = \gamma_1 N_\xi^2$ and $\text{nnz}(G_m) = \gamma_2 N_\xi^2$ with $0 < \gamma_1, \gamma_2 \ll 1$, the cost per iteration of the classical CG method scales as

$$O((M + 1)(\gamma_1 N_\xi^2 N_\xi + \gamma_2 N_\xi^2 N_A)).$$

(9)

In sparse CG algorithms, the cost at iteration $k$ is essentially related to three matrix-vector products, $Ap^k$ plus two extra products in the MGS step. In contrast to classical CG algorithms, the sparse direction $p^k$ is a (very) sparse vector that has $N_A + S_k$ non-zero entries with $S_k = m_1 + m_2 + \cdots + m_k$ for $k \geq 1$ and $S_0 = 0$. Since $p^k$ has $N_A + S_k$ non-zeros (with $N_A$ first non-zeros), the number of non-zero columns in $p^k$ is equal to $C_k \leq \min(1 + S_k, N_\xi)$. For $k$ large enough, the sparse mask may be entirely filled, in which case sparse CG becomes classical CG with $C_k = N_\xi$. When $k$ is relatively small, it is expected that $p^k$ is sparse, in which case the cost of $A_m p^k$ is $O(\text{nnz}(A_m) C_k)$ with $C_k \ll N_\xi$. Since $A_m$ is sparse and $p^k$ is very sparse, the matrix $A_m p^k$ will also be very sparse. Denoting the number of non-zero rows in $A_m p^k$ by $R_k$, the cost of the matrix product $(A_{m} p^k)G_m$ is $O(\text{nnz}(G_m) R_k)$ with $R_k \ll N_A$. As a result, the cost of the sparse CG algorithm at a (relatively small) iteration $k$ is

$$O(3(M + 1)(\gamma_1 N_\xi^2 C_k + \gamma_2 N_\xi^2 R_k)).$$

(10)

The additional inner products used in the MGS step are not taken into account as their cost is significantly lower than matrix-vector products. Depending on the level of sparsity of the matrices $A_m$ and $G_m$, the ratio of costs at the $k$-th sparse CG iteration scales as follows in Table 1.
We next discuss the storage requirements of both algorithms. At each iteration, the classical CG algorithm requires five dense vectors \((u^0, p^0, Ap^0, r^0, r^0)\) to be saved, meaning that \(5N_N\) entries need to be stored. In the sparse CG algorithm, we have to save \(2l + 3\) vectors, of which \(l + 1\) dense vectors \((r^k and \((Ap^k)_{j=k-l,...,k})\) and \(l + 2\) sparse vectors \((u^k, m^k and \((p^k)_{j=k-l,...,k})\). The storage requirements are summarized in Table 2.

In practice, the parameter \(l\) is kept small. In our numerical studies, \(l = 3\), meaning that 4 dense and 5 sparse vectors are stored at each sparse CG iteration, instead of 5 dense vectors in classical CG algorithms, which roughly represents 20% memory saving.

### 3.2. Convergence analysis

It is of interest to note that the sparse CG algorithm is convergent. If \(\overline{m}\) denotes the average number of new entries added in the sparse mask at each iteration, then \(\left\lceil \frac{2N_N N_N - N_N}{\overline{m}} \right\rceil\) iterations are needed to fill up entirely the sparse mask (assuming the \(N_N\) first entries of the initial sparse mask are non-zeros). Once the sparse mask is fully dense, the sparse CG algorithm becomes a classical CG method, which is known to converge in at most \(N_N\) iterations. As a result, the sparse CG algorithm converges at most \(\left\lceil \frac{2N_N N_N - N_N}{\overline{m}} \right\rceil + N_N = \left\lceil \frac{N_N}{\overline{m}} \right\rceil (m + 1) - 1\) iterations.

We now provide some theoretical analysis of the proposed sparse CG algorithm using the framework of inexact Krylov subspace methods studied in [26,27]. To this end, we first show that the sparse CG algorithm is a projection method on inexact Krylov subspaces. The sparse CG algorithm generates subspaces of the form

\[
\text{span}\{m^0 \circ r^0, m^1 \circ (A(m^0 \circ r^0)), m^2 \circ (A(m^1 \circ (A(m^0 \circ r^0)))), \ldots\}. \tag{11}
\]

Defining \(m^0 \circ m^0\), it can be seen that \(m^1 \circ (A(m^0 \circ r^0)) = A_1(v)\) with \(A_1 = (m^1 \otimes 1^T) \circ A\), where \(1 = (1, 1, \ldots, 1)^T \in \mathbb{N}^{N_N N_N}\). Similarly, \(m^2 \circ (A(m^0 \circ r^0)) = m^2 \circ A_2(v) = A_2(v)\) with \(A_2 = (m^2 \otimes 1^T) \circ A\). Hence, the sparse CG algorithm generates subspaces of the form \(\text{span}\{v, A_1(v), A_2(v), \ldots\}\) since sparse masks have their entries \(m^k\) equal to zero (resp. one) for \(i \in \mathcal{J}^k\) (resp. \(i \notin \mathcal{J}^k\)), each matrix \(A_k\) can be written as \(A_k = A + E_k\) as in [26,27], with perturbation matrices given by

\[
E_k(i, j) = \begin{cases} 
0 & \text{if } i \notin \mathcal{J}^k, \\
-a_{ij} & \text{if } i \in \mathcal{J}^k.
\end{cases}
\]

As iterations \(k\) increase \(m^k \to 1\), meaning that \(\mathcal{J}^k \to \emptyset\), \(E_k \to 0\) and \(A_k \to A\). As such, the sparse CG algorithm generates inexact Krylov subspaces as in [27], where sequences of perturbed matrices \(A_k\) such that \(\lim_{k \to 0} A_k = A\) were considered.

Since the classical CG method is equivalent to the Full Orthogonalization Method (FOM) used within Arnoldi’s procedure in the symmetric case, the sparse CG algorithm can be analyzed within the framework of inexact Krylov subspace methods. Following [26], we consider the inexact Arnoldi procedure

\[
AV_m = V_{m+1}H_m - [E_1v_1, E_2v_2, \ldots, E_mv_m],
\]

where \(H_m \in \mathbb{R}^{(m+1) \times m}\) and \(V_m = [v_1, \ldots, v_m] \in \mathbb{R}^{N_N N_N \times m}\) is such that \(V_m^TV_m = I\). When \(A\) is symmetric, the Arnoldi process coincides with the Lanczos process, that is \(H_m = (H_m)_{m+1:1,m+1}\) is symmetric tridiagonal. At the \(m\)-th iteration \((m \geq 1)\) the “true residual” is defined as \(r^m = b - Au^m = b - A(u^0 + V_m y_m) = r^0 - AV_m y_m\) with \(r^0 = b - Au^0\) and \(v_1 = r^0/\|r^0\|_2\). By contrast, the “truncated residual” is given by \(r^m = r^0 - V_m y_m + H_m y_m\), which yields \(r^m = r^0 + E_1v_1 + \ldots + E_mv_m y_m\) for \(m \geq 1\), with \(r^0 = r^0\). A natural assumption used in [26] is that the perturbation terms satisfy \(||E_1v_1, \ldots, E_mv_m y_m||_2 < \gamma \|A\|_2\), where \(\|A\|_2 = \sup(||Ax||_2, ||x||_2 = 1)\) and \(\gamma \in (0, 1)\). When applied to vectors, \(||\cdot||_2\) denotes the Euclidean norm, i.e. \(||x||_2 = (x^T x)^{1/2}\).

We now provide a bound for the perturbation terms when \(y_m\) is computed using FOM as \(y_m^{\text{FOM}} = H_m^{-1}(\beta e_1)\), where \(\beta = ||r^0||_2, e_1 = (1, 0, \ldots, 0)^T \in \mathbb{R}^m\).
Lemma 3.1. If the eigenvalues of $A$ are such that $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{N_u} N_L$ without being all equal, the perturbation terms $\|\|E_1 v_1, \ldots, E_m v_m\|_{ym}^{\text{form}}\|_2$ in the sparse CG algorithm satisfy $\|\|E_1 v_1, \ldots, E_m v_m\|_{ym}^{\text{form}}\|_2 \leq \gamma \|A\|_2$ with

$$
\gamma = \frac{m(c_{m-1}(1 + 2\rho_1))^4}{(\lambda_1 - \lambda_{N_u} N_L)^2} \sin^4(\theta_1) \left( \sum_{k=1}^{m} \|\|E_k\|_2\|\|v_k v_k^T\|_2\|\|v_m y_m\|_2 \right)^{1/2},
$$

where $c_{m-1}$ is the Chebyshev polynomial of the first kind of degree $m - 1$, $\rho_1 = \frac{\lambda_1 - \lambda_2}{\lambda_2 - \lambda_{N_u} N_L}$, and $\theta_1$ is the angle between $v_1$ and the eigenvector of $A$ corresponding to $\lambda_1$.

Proof. Since $v_i$ are orthonormal vectors, it holds

$$
\|\|E_1 v_1, \ldots, E_m v_m\|_{ym}^{\text{form}}\|_2 = \left( \sum_{k=1}^{m} \|\|E_k\|_2\|\|v_k v_k^T\|_2\|\|v_m y_m\|_2 \right)^{1/2}.
$$

Using [26, Lemma 5.2] for estimating the FOM components in the inexact Lanczos procedure, and using the fact that $\|\|E_k\|_2 \leq \|A\|_2$ for any symmetric matrix $A$, it follows that

$$
\|\|E_1 v_1, \ldots, E_m v_m\|_{ym}^{\text{form}}\|_2 \leq m\|A\|_2 \|\|y_m^{\text{form}}\|_2 \leq \frac{m\|A\|_2}{\lambda_{\text{max}}(H_m)} \left( \sum_{k=1}^{m} \|\|E_k\|_2\|\|r_k^{\text{form}}\|_2 \right)^{1/2},
$$

where we use $\lambda_{\text{max}}(\tilde{H}_m) = \lambda_{\text{max}}(H_m)$ for symmetric matrices. According to Kaniel-Paige’s convergence theory [14], the largest eigenvalue of $\tilde{H}_m$ in the Lanczos procedure can be estimated as

$$
\lambda_1 \geq \lambda_{\text{max}}(\tilde{H}_m) \geq \frac{(\lambda_1 - \lambda_{N_u} N_L) \tan^2(\theta_1)}{(c_{m-1}(1 + 2\rho_1))^2},
$$

which leads to (13).

Remark 1. The coefficient $\gamma$ is expected to be small since $\|\|r_k^{\text{form}}\|_2$ is globally (but not necessarily monotonically) decreasing as long as $\text{Im}(V_{m+1} H_m)$ keeps growing, see [26, Remark 3.4]. In exact arithmetic $\|\|r_k^{\text{form}}\|_2 \rightarrow 0$ since $\|\|r_k^{\text{form}}\|_2 \leq \|\|r_k^{\text{form}}\|_2$ and the true residual norm is known to tend to zero in the CG case.

Remark 2. We discuss the finiteness of the coefficient $\gamma$. First, $\lambda_1 = \lambda_{N_u} N_L$ would correspond to the case when $A = \lambda_1 I$, for which solving (3) is not of interest. Second, expanding $v_1$ in the set of (orthonormal) eigenvectors as $v_1 = \sum_i d_i z_i$, with $d_i = v_i^T z_i$, it holds $1 = \|v_1\|_2^2 = \|d\|_2^2$. Since $\cos(\theta_1) = z_1^T v_1 = d_1$ and $\sin(\theta_1) = \frac{1 - d_1^2}{d_1^2}$, then $\tan^2(\theta_1) = 0 \Rightarrow v_1 = \pm z_1$. As such, $\tan^2(\theta_1) = 0$ never holds as it would mean that $v_1$ and $z_1$ are collinear, which is highly unlikely in practice. Lastly, when considering stochastic Galerkin matrix equations corresponding to stochastic diffusion models (1), the coefficient $\rho_1$ is extremely small, since the largest eigenvalues of $A$ are tightly clustered for those models. As a result, the terms $c_{m-1}(1 + 2\rho_1)$ increase very slowly with $m$. In summary, $\gamma$ does not diverge for those stochastic Galerkin matrix equations.

Remark 3. The idea proposed here can be extended to nonsymmetric stochastic Galerkin matrix equations using a sparse variant of the GMRES method. When using GMRES, that is $y_m^{\text{gm}} = \arg \min_{y \in \mathbb{R}^m} \|H_m y - b e_1\|_2$, the norm of the perturbation is bounded as

$$
\|\|E_1 v_1, \ldots, E_m v_m\|_{ym}^{\text{form}}\|_2 \leq m\|A\|_2 \|\|y_m^{\text{gm}}\|_2 \leq \frac{m\|A\|_2}{\sigma_{\text{max}}(H_m)} \left( \sum_{k=1}^{m} \|\|r_k^{\text{gm}}\|_2 \right)^{1/2},
$$

using [26, Lemma 5.1].

\footnote{The CG residual norm is such that $\|\|r\|_2 \leq C(A, b, u)\|u^* - u\|_A$, where $u$ is the exact solution, $b$ is the right-hand side, $\|\cdot\|_A$ is the energy norm $\|x\|_A = (x^T A x)^{1/2}$ and $C(A, b, u)$ is a constant that is independent of $u^*$. Since $\|u^* - u\|_A \leq 2 \left( \frac{\|u^*\|_A^2}{\|u^*\|_A^2 + \|u\|_A^2} \right)^{1/2}$, the CG residual norm tends to zero.}
Since the proposed sparse CG algorithm fits within the framework of inexact Krylov-based methods, we can use some of the results derived in [26]. For example, the distance between the true and truncated residuals after \( m \) iterations of the sparse CG algorithm is such that

\[
||r^m - \tilde{r}^m||_2 \leq \sum_{k=1}^{m} |e_k^T y_m^{\text{form}}| ||E_k||_2.
\]

(14)

In contrast to the classical Arnoldi method, the true residual in sparse CG algorithms is not orthogonal to the basis vectors \((v_i)_{i=1,...,m}\). The loss of orthogonality can be estimated as

\[
||V_m^T r^m||_2 \leq \sum_{k=1}^{m} |e_k^T y_m^{\text{form}}| ||E_k||_2.
\]

(15)

Equations (14) and (15) suggest that if the components \(|e_k^T y_m^{\text{form}}|\) tend to decrease across iterations, then the perturbations \(||E_k||_2\) are allowed to grow (see [26] for more details).

4. Numerical experiments

To illustrate, we consider randomly parametrized diffusion models (1) defined on two-dimensional spatial domains with homogeneous Dirichlet boundary conditions and deterministic source terms using the S-IFISS Matlab toolbox [4]. For different test cases, we compare the sparse CG algorithm to the classical CG method in terms of convergence and timings. For a fair comparison, we use the same block-diagonal preconditioner \( M = G_0 \otimes A_0 \) (see [21]) in both CG algorithms. Simulations were performed using sequential Matlab solvers on a single core of a machine with dual quad Intel Core i5-7500U processors and 8 Gb RAM.

First, we focus on favorable cases when the sought discretized solutions are sparse. To create a sparse solution, we define \( w \in \mathbb{R}^{N_x N_t} \) with components chosen randomly from \([-1,1]\) and then nullify the \( w_i \) that are smaller than a given value (say, 0.95) for \( i > N_x \). This provides a sparse vector \( u \) from which a right-hand side \( b = Au \) is computed, where \( A \) is the discretized diffusion matrix provided by S-IFISS. We manufacture sparse solutions in this way for several S-IFISS test cases, namely problem #2 (where \( D = [-1,1]^2 \), standard deviation \( \sigma = 0.525 \) in the KL expansion) and problems #3 and #4 (where \( D = [-2,2] \times [-1,1] \) and \( \sigma = 0.515 \)). For each problem, we consider \( M = 5 \) random variables and 4-th PC order, meaning that \( N_t = 126 \).

Timings and numbers of iterations are reported in Table 3, showing that the sparse CG algorithm runs faster than the classical CG method with up to roughly twenty times reduction in computational cost. To illustrate, the convergence of the classical/sparse CG algorithm is shown in Figs. 1 and 2. It is to be noted that the choice made for \( \varepsilon_{\text{tol}} \) generally affects the convergence of the sparse CG algorithm (see, for example, Fig. 1).

Another important aspect of the sparse CG algorithm concerns its ability to recover the sparsity pattern (if any) of the sought solution. Recasting discretized sparse CG solutions \( \tilde{u} \in \mathbb{R}^{N_x N_t} \) as \( \tilde{U} = [\alpha_1, \ldots, \alpha_{N_t}] \in \mathbb{R}^{N_x \times N_t} \) with \( \alpha_i = (\alpha_{i,1}, \ldots, \alpha_{i,N_x})^T \), stochastic solutions are built at each FE node \( x_j \) as \( \hat{u}(x_j, \xi) = \sum_{i=1}^{N_t} \alpha_{i,j} \psi_i(\xi). \) For each index \( j = 1, 2, \ldots, N_x \), the \( \gamma \)-sparsity of \( \hat{u} \) at \( x_j \) is defined as the number of significant PC coefficients

\[
\# \{i \text{ such that } |\alpha_{i,j}| > \gamma \}. \quad (16)
\]

In Fig. 3, the \( \gamma \)-sparsity of the sparse CG solution as a function of the spatial coordinates is represented for S-IFISS problem #2, showing that the sparse structure of the exact solution is almost recovered by the sparse CG algorithm. This attractive feature (referred to as the "bet of sparsity principle" [15] in the literature) of sparse CG algorithms explains its computational efficiency compared to that of classical CG methods, since it naturally exploits the underlying sparsity (if any) of the sought solution. As another illustration of this feature, we compare the exact sparsity recovery (\( \gamma = 0 \)) of sparse manufactured solutions for various S-IFISS test cases. The preconditioned sparse CG algorithm recovers almost exactly the sparse structure of the exact solutions, by contrast with the classical CG method, which always provides dense solutions (see Table 4).

We finally compare both CG algorithms while approximating the solution to the stochastic diffusion equation. We consider the most challenging S-IFISS test-case, namely problem #2 with the source term given by \( f(x) = \frac{1}{2}(2 - x_1^2 - x_2^2) \). We use
$\varepsilon_{lv} = 10$

$\varepsilon_{lv} = N_x N_\xi / 100 = 1210$

Fig. 1. S-IFISS problem #2 with $M = 5$, $N_x = 961$, $N_\xi = 126$, $\sigma = 0.525$ and sparse manufactured solutions: convergence of preconditioned classical/sparse CG algorithms with $\varepsilon = 10^{-6}$, $\theta_{init} = 10$ and different values of $\varepsilon_{lv}$.

Fig. 2. S-IFISS problems #3 (left) and #4 (right) with sparse manufactured solutions, $M = 5$, $N_x = 1023$, and $\sigma = 0.515$: Convergence of preconditioned classical/sparse CG algorithms with $\varepsilon = 10^{-6}$, $\theta_{init} = 10$ and $\varepsilon_{lv} = 10$ in sparse CG.

$M = 5$ random variables and 4-th PC order (i.e. $N_\xi = 126$), a stretched mesh grid made of $N_x = 961$ points and $\sigma = 0.525$. As can be seen in Fig. 4, both CG algorithms converge similarly, indicating the fact that there is no underlying sparsity in the sought solution. This suggests that the sparse CG algorithm reduces to the classical CG method when considering SPDE models with non-sparse solutions, which is in agreement with the convergence property of sparse CG (see section 3.2). It is worth mentioning that even if the convergence of both algorithms looks comparable, the sparse CG algorithm still runs three times faster than the classical CG method.
5. Conclusions

In this work, we proposed a sparse CG algorithm for efficiently solving matrix equations arising from stochastic Galerkin projection schemes. The sparse CG algorithm is proved to be convergent and has a lower abstract computational cost compared to that of the classical CG method. Numerical studies conducted on stochastic diffusion models show that the sparse CG algorithm can provide substantial speedups when the exact solution has a sparse representation in a PC basis set. In such cases, the sparse structure of the SPDE solutions is almost recovered, which allows for significant reductions in computational cost compared to the classical CG method. This suggests that the proposed sparse CG algorithm has the potential to efficiently approximate solutions to SPDE models with localized uncertainties. For non-sparse solutions, the sparse CG algorithm displays similar convergence trends as the classical CG method, which is in agreement with the convergence property of the sparse CG algorithm.

Further numerical studies would be required to compare more precisely sparse and classical CG algorithms for a wider class of SPDEs. The idea proposed here can also be used to formulate a sparse variant of the GMRES algorithm with applications to nonsymmetric stochastic Galerkin matrix equations. Interestingly, the sparse CG algorithm can also be used for solving nonlinear SPDEs. The full discretization of such SPDEs leads to systems of non-linear equations of the form \( f(u) = 0 \) that can be solved in a Newton-like fashion. At each iteration, the sparse CG algorithm can be used for solving the (potentially large-scale) matrix equations for the Newton step, \( f'(u^k)\delta^k = -f(u^k) \), where \( f(u) \) is the Jacobian matrix of \( f \). Using this
approach, it is expected to obtain sparse approximate solutions that would be computationally advantageous for nonlinear SPDE models whose solution admits a sparse representation in a PC basis set.
